The MAKET-ANI detector is operating at altitude 3200 m., at slope of mt. Aragats in Armenia. More than million showers with size, greater than $10^5$ were registered, by the MAKET-ANI detector in 1999-2004. Detector has effectively collected the cores of EAS, initiated by primaries with energies of $5 \times 10^{14} - 3 \times 10^{17}$ eV. After proving that the quality of the reconstruction of the EAS size and shape are reasonably good we present the LDF functions for the distances up to 120 m. from EAS core. The obtained LDF functions are compared with CORSIKA562 (QGS JET, NKG) [1,2] simulations. Proceeding from the dependences of shower age on shower size we discuss the mass composition models supported by experimental evidence.

1. Introduction

The MAKET-ANI surface array [3,4] consists of 92 particle density detectors formed from plastic scintillators with thickness of 5 cm. Twenty four of them have area 0.09 m² and 68 have area of 1 m². The central part consists of 73 scintillation detectors and is arranged in a rectangle of 85 x 65 m². Two peripheral points of a distance of 95m and 65m from the center of the installation consist of 15 and 4 scintillators respectively. In order to estimate the zenith and azimuth angles 19 detectors from 92 (with area 1m²) are equipped with timing readout measuring the EAS front appearance with an accuracy of ~ 5 ns. The photomultipliers (PM-49) are placed in light-tight iron boxes. Logarithmic amplitude-digital converters (ADC) and constant fraction discriminators (CFD) are assembled just above PM. The dynamic range of the registered particle number is ~ $5 \times 10^3$.

The normalization from PM amplitude to number of particles is performed by calibration spectrum with mode equal to 11 MeV. The transition from “scintillation” densities to “electronic” ones is made by [5]:

$$\rho_\text{sc}(r)/\rho_\text{e}(r) = (r/R_M)^\alpha,$$

where $\alpha = -0.18$ and $R_M$ is Molier radii.

The Nishimura-Kamata Greizen approximation is used for Extensive Air Shower (EAS) characteristic estimation [6]:

$$\rho_s(r) = \frac{N_e}{2 \cdot \pi \cdot R_M^2} \cdot C(s) \cdot \left(\frac{r}{R_M}\right)^{(s-2)} \cdot \left(\frac{r}{R_M} + 1\right)^{(s-4.5)},$$

where $\rho_s(r)$ is the particle density on the distance $r$ from shower axes, $N_e$ – total number of shower electrons, $R_M = 118\text{m}$ – Molier radii, $s$ – shower age parameter and $C(s)$=0.366 s²(2.07-s)¹²⁵ [7].

The uncertainties of the reconstruction of EAS parameters are as following: shower size $\Delta N_e < 10\%$, the shower shape (age) parameter $\Delta s < 0.06$. The accuracies of EAS angles determination are: $\Delta \theta < 1.5\degree$ and $\Delta \phi < 5\degree$ [8].
Monte-Carlo calculations with CORSIKA562 (QGSJET, NKG) confirmed that EAS with sizes $N_e > 5 \cdot 10^4$ and core, located within the rectangle of $20 \times 44 m^2$, are selected with efficiency $\varepsilon \geq 95\%$. Showers are initiated by primary ions with energies greater than $3 \cdot 10^6$ GeV (see Figure 1).

![Figure 1. Efficiency of the MAKET-ANI detector for the showers localized in area of (20 x 44) m²](image)

2. The Lateral Distribution Function (LDF) of shower particles.

In the period of 1998 - 2004 approximately $1.2 \cdot 10^7$ showers were registered with effective registration time of about $1.34 \cdot 10^8$ sec. From these showers ~ 1,200,000 events only were selected for the further treatment. We selected EAS cores from more compact area around the geometrical center of MAKET-ANI detector, ensuring high efficiency of EAS registration. The following cuts were applied for the events selection: $N_e > 10^5$, $0.3 < s < 1.7$, core position within area providing efficiency $\varepsilon \geq 95\%$, $\theta < 46.8^\circ$. The LDF functions were estimated in the 5 zenith angle intervals, uniformly distributed according to $\text{Sec}(\theta)$ and in logarithmic uniform intervals distributed according to $N_e$ ($\Delta \text{Lg}(N_e) = 0.3$). The distribution of the discrepancies (biases) between densities estimated by formula (1) and measured densities for all detector locations were calculated. The accuracy of the approximation function (1) turns out not worse than $\pm 5\%$ [9].

In the Table 1 the “averaged” and approximated shower parameters are presented for the near vertical ($\theta \leq 23.8^\circ$) showers. First 4 columns of Table 1 contain number of used showers, mean logarithm of shower size, mean age parameter and MSD of age. In the next columns the same averaged parameters, but obtained with approximation of LDF, are posted. Till shower sizes up to $N_e = 10^6 \pm 3$ the approximation parameters fit the data very well, for larger shower sizes we exclude from approximation procedures detectors at near distances to avoid saturation effects.

Figure 2. Observed LDF functions in comparison with simulated by CORSIKA 562(QGSJET, KNG).

In Figure 2 near vertical (θ≤23.8°) LDF functions, measured in 7 $N_e$ intervals, are presented. The simulated LDF are noted by asterisks. Detector response function was calculated using CORSIKA simulations. $2 \times 10^6$ events for each of 5 primary nuclei (H, He, O, Si, Fe) in the zenith angle range of 0-50°, for height of 700 g/cm², for energy starting from $10^{14}$ eV were simulated. Shower particles were followed till thresholds 3 MeV for electrons; 50 MeV for muons, 100 MeV for hadrons. Energy spectra has index $\gamma_1 = -2.7$, before knee and $\gamma_2 = -3.1$ after knee for all nuclei. The knee position was simulated according to $E_{knee} = Z \cdot E_0$, $E_0 = 3 \times 10^{15}$ eV, $Z$ is the charge of primary nuclei. The mass composition was taken as “normal” (36% H, 25% He, 14% O, 15% Si, 10% Fe) [10]. Simulated events undergo all procedures of experimental data analysis. Remarkable agreement of experimental and simulated LDF functions pointed on the correct treatment of transition effects in the scintillators.

3. Discussion

In Figure 3 we present the experimental dependence of age parameter on shower size in comparison with simulations for pure proton and iron composition. To compare experimental dependence with models we consider following possibilities:

1. “Normal” composition (36%P, 25%He, 14%O, 15%Si, 10%Fe) [10], knee position $E_{knee} = Z \cdot 3 \times 10^{15}$ eV - red solid;
2. “Normal” composition with fixed knee position $E_{knee} = 3 \times 10^{15}$ eV for all nuclei - red dashed;
3. “Heavy” composition (5%P, 5%He, 10%O, 10%Si, 70% Fe) [11], knee position $E_{knee} = Z \cdot 3 \times 10^{15}$ eV – green.
As we see from the Figure 3 first option fits experimental data rather well, therefore we can exclude options 2 and 3.
